## Abstract

The problem of making bounded in-degree and out-degree data structures partially persistent is considered. The node copying method of Driscoll *et al.* is extended so that updates can be performed in *worst-case* constant time on the pointer machine model. Previously it was only known to be possible in amortised constant time [2].

The result is presented in terms of a new strategy for Dietz and Raman's dynamic two player pebble game on graphs.

It is shown how to implement the strategy and the upper bound on the required number of pebbles is improved from $2b + 2d + O(\sqrt{b})$ to $d + 2b$, where $b$ is the bound of the in-degree and $d$ the bound of the out-degree. We also give a lower bound that shows that the number of pebbles depends on the out-degree $d$.

# Introduction

This paper describes a method to make data structures partially persistent. A partially persistent data structure is a data structure in which old versions are remembered and can always be inspected. However only the latest version of the data structure can be modified.

An interesting application of a partially persistent data structure is given in [4] where the planar point location problem is solved by an elegant application of partially persistent search trees. The method given in [4] can be generalised to make arbitrary bounded in-degree data structures partially persistent [2].

As in [2], the data structures we consider will be described in the pointer machine model, i.e. they consist of records with a constant number of fields each containing a unit of data or a pointer to another record. The data structures can be viewed as graphs with bounded out-degree. In the following let $d$ denote this bound.

The main assumption is that the data structures also have **bounded in-degree**. Let $b$ denote this bound. Not all data structures satisfy this constraint — but they can be converted to do it: Replace nodes by convergent binary balanced trees, so that all original pointers that point to a node now instead points to the leafs in the tree substituted into the data structure instead of the node, and store the node's original information in the root of the tree. The assumption can now be satisfied by letting at most a constant number of pointers point to the same leaf. The drawback of this approach is that the time to access a node $v$ is increased from $O(1)$ to $O(\log b_v)$ where $b_v$ is the original bound of the in-degree of $v$.

The problem with the method presented in [4, 2] is that an update of the data structure takes **amortised** time $O(1)$, in the worst case it can be $O(n)$ where $n$ is the size of the current version of the data structure.

In this paper we describe how to extend the method of [4, 2] so that an update can be done in **worst case** constant time. The main result of this paper is:

**Theorem 1** *It is possible to implement partially persistent data structures with bounded in-degree (and out-degree) such that each update step and access step can be performed in* worst case *time $O(1)$.*

The problem can be restated as a dynamic two player pebble game on dynamic directed graphs, which was done by Raman and Dietz in [1]. In fact, it is this game we consider in this paper.

The central rules of the game are that player **I** can add a *pebble* to an arbitrary node and player **D** can remove all pebbles from a node provided he places a pebble on all of the node's predecessors. For further details refer to Sect. 2. The goal of the game is to find a strategy for player **D** that can guarantee that the number of pebbles on all nodes are bounded by a constant $M$. Dietz and Raman gave a strategy which achieved $M \leq 2b + 2d + O(\sqrt{b})$ — but they were not able to implement it efficiently which is necessary to remove the amortisation from the original persistency result.

In this paper we improve the bound to $M = d + 2b$ by a simple modification of the original strategy. In the static case (where the graph does not change) we get $M = d + b$.

We also consider the case where the nodes have different bounds on their in- and out-degree. In this case we would like to have $M_v = f(b_v, d_v)$ where $f : N^2 \rightarrow N$ is a monotonically increasing function. Hence only nodes with a high in-degree should have many pebbles. We call strategies with this property for *locally adaptive*. In fact, the strategy mentioned above satisfies that $M_v = d_v + 2b_v$ in the dynamic game and $M_v = d_v + b_v$ in the static game.

By an efficiently implementable strategy we mean a strategy that can be implemented such that the move of player **D** can be performed in time $O(1)$ if player **D** knows where player **I** performed his move. In the following we call such strategies implementable.

The implementable strategies we give do not obtain such good bounds. Our first strategy obtains $M = 2bd + 1$, whereas the second is locally adaptive and obtains $M_v = 2b_v d_v + 2b_v - 1$.

The analysis of our strategies are all tight — we give examples which match the upper bounds. The two efficiently implementable strategies

have simple implementations, so no large constants are involved in the implementations.

We also give lower bounds for the value of $M$ which shows that $M$ depends both on $b$ and $d$ for all strategies. More precisely we show that[1]:

$$M \geq \max\{b + 1, \lfloor \alpha + \sqrt{2\alpha - 7/4} - 1/2 \rfloor, \left\lceil \frac{\log \frac{2}{3}d}{\log \log \frac{2}{3}d} - 1 \right\rceil\},$$

where $\alpha = \min\{b, d\}$.

Section 1 describes the method presented in [4, 2]. Section 2 defines the dynamic graph game of [1]; Sect. 3 gives the new game strategy for player **D** which is implementable; Sect. 4 describes the technical details which are necessary to implement the strategy from Sect. 3; Sect. 5 analyses the strategy of Sect. 3 and 4; Sect. 6 gives a locally adaptive strategy; Sect. 7 gives a locally adaptive strategy which is implementable; finally Sect. 8 gives a lower bound for $M$.

# 1 The node copying method

In this section we briefly review the method of [4, 2]. For further details we refer to these articles. The purpose of this section is to motivate the game that is defined in Sect. 2, and to show that if we can find a strategy for this game and implement it efficiently, then we can also remove the amortisation from the partially persistency method described below.

The *ephemeral data structure* is the underlying data structure we want to make partially persistent. In the following we assume that we have access to the ephemeral data structure through a finite number of entry pointers. For every update of the data structure we increase a version counter which contains the number of the current version.

When we update a node $v$ we cannot destroy the old information in $v$ because this would not enable us to find the old information again. The idea is now to add the new information to $v$ together with the

---

[1]We define $\log x = \max\{1, \log_2 x\}$

4

current version number. So if we later want to look at an old version of the information, we just compare the version numbers to find out which information was in the node at the time we are looking for. This is in very few words the idea behind the so called *fat node* method.

An alternative to the previous approach is the *node copying* method. This method allows at most a constant number ($M$) of additional information in each node (depending on the size of $b$). When the number of different copies of information in a node gets greater than $M$ we make a copy of the node and the old node now becomes *dead* because new pointers to the node has to point to the newly created copy. In the new node we only store the information of the dead node which exists in the current version of the ephemeral data structure. We now have to update all the nodes in the current version of the data structure which have pointers that point to the node that has now become dead. These pointers should be updated to point to the newly created node instead — so we recursively add information to all the predecessors of the node that we have copied. The copied node does not contain any additional information.

# 2   The dynamic graph game

The game Dietz and Raman defined in [1] is played on a directed graph $G = (V, E)$ with bounded in-degree and out-degree. Let $b$ be the bound of the in-degree and $d$ the bound of the out-degree. W.l.o.g. we do not allow the existence of self loops and multiple edges. To each node a number of pebbles is associated, denoted by $P_v$. The *dynamic graph game* is now a game where two players **I** and **D** alternate to move. The moves they can perform are:

Player **I**:

    **a)** add a pebble to an arbitrary node $v$ of the graph or

    **b)** remove an existing edge $(v, u)$ and create a new edge $(v, w)$ without violating the in-degree constraint on $w$, and place a pebble on the node $v$.

Player **D**:

    **c)** do nothing or

    **d)** remove all pebbles from a node $v$ and place a new pebble on all the predecessors of $v$. In the following $\text{ZERO}(v)$ performs this operation.

The goal of the game is to show that there exists a constant $M$ and a strategy for player **D** such that, whatever player **I** does, the maximum number of pebbles on any node after the move of player **D** is bounded by $M$.

In the static version of the game player **I** can only do moves of type a).

The existence of a strategy for player **D** was shown in [1], but the given strategy could not be implemented efficiently (i.e. the node $v$ in d) could not be located in time $O(1)$).

**Theorem 2 (Dietz and Raman [1])** *A strategy for player* **D** *exists that achieves* $M = O(b + d)$.

# 3   The strategy

We now describe our new strategy for player **D**. We start with some definitions. We associate the following additional information with the graph $G$.

- Edges are either *black* or *white*. Nodes have at most one incoming white edge. There are no white cycles.

- Nodes are either *black* or *white*. Nodes are white if and only if they have an incoming white edge.

The definitions give in a natural way rise to a partition of the nodes into components: two nodes connected by a white edge belong to the same component. It is easily seen that a component is a rooted tree of white edges with a black root and all other nodes white. A single
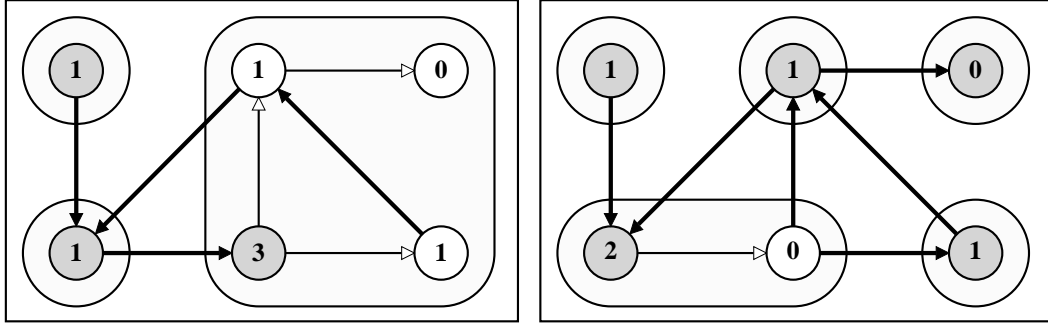

6

Figure 1: The effect of performing a BREAK operation. The numbers are the number of pebbles on the nodes.

black node with no adjacent white edge is also a component. We call this a simple component. See Fig. 1 for an example of a graph with two simple components and one non simple component.

To each node $v$ we associate a queue $Q_v$ containing the predecessors of $v$.

The central operation in our strategy is now the following BREAK operation. $C_v$ denotes the component containing $v$.

> **procedure** BREAK($C_v$)
>     $r \leftarrow$ the root of $C_v$
>     colour all nodes and edges in $C_v$ black
>     **if** $Q_r \neq \emptyset$ **then**
>         colour $r$ and (ROTATE($Q_r$), $r$) white
>     **endif**
>     ZERO($r$)
> **end**.

The effect of performing BREAK on a component is that the component is broken up into simple components and that the root of the original component is appended to the component of one of its predecessors (if any). An example of the application of the BREAK operation is shown in Fig. 1.

A crucial property of BREAK is that all nodes in the component change colour (except for the root when it does not have any predecessors, in this case we per definition say that the root changes its colour twice).

7

Our strategy is now the following (for simplicity we give the moves of player **I** and the counter moves of player **D** as procedures).

**procedure** ADDPEBBLE($v$)
    place a pebble on $v$
    BREAK($C_v$)
**end**.

**procedure** MOVEEDGE($(v, u), (v, w)$)
    place a pebble on $v$
    **if** $(v, u)$ is white **then**
        BREAK($C_v$)
        DELETE($Q_u, v$)
        replace $(v, u)$ with $(v, w)$ in $E$
        ADD($Q_w, v$)
    **else**
        DELETE($Q_u, v$)
        replace $(v, u)$ with $(v, w)$ in $E$
        ADD($Q_w, v$)
        BREAK($C_v$)
    **endif**
**end**.

In MOVEEDGE the place where we perform the BREAK operation depends on the colour of the edge $(v, u)$ being deleted. This is to guarantee that we only remove black edges from the graph (in order not to have to split components).

Observe that each time we apply ADDPEBBLE or MOVEEDGE to a node $v$ we find the root of $C_v$ and zero it. We also change the colour of all nodes in $C_v$ — in particular we change the colour of $v$. Now, every time a black node becomes white it also becomes zeroed, so after two **I** moves have placed pebbles on $v$, $v$ has been zeroed at least once. That the successors of a node $v$ cannot be zeroed more than $O(1)$ times and therefore cannot place pebbles on $v$ without $v$ getting zeroed is shown in Sect. 5. The crucial property is the way in which BREAK colours nodes and edges white. The idea is that a successor $u$ of $v$ cannot be

8

zeroed more than $O(1)$ times before the edge from $(v, u)$ will become white. If $(v, u)$ is white both $v$ and $u$ belong to the same component, and therefore $u$ cannot change colour without $v$ changing colour.

In Sect. 4 we show how to implement **BREAK** in worst case time $O(1)$ and in Sect. 5 we show that the approach achieves that $M = O(1)$.

# 4   The new data structure

The procedures in Sect. 3 can easily be implemented in worst case time $O(1)$ if we are able to perform the **BREAK** operation in constant time. The central idea is to represent the colours indirectly so that all white nodes and edges in a component points to the same variable. All the nodes and edges can now be made black by setting this variable to black.

A *component record* contains two fields. A colour field and a pointer field. If the colour field is white the pointer field will point to the root of the component.

To each node and edge is associated a pointer $cr$ which points to a component record. We will now maintain the following invariant.

- The $cr$ pointer of each black edge and simple component will point to a component record where the colour is black and the root pointer is the null pointer. Many simple components can share the same component record.

- For each non simple component there exist exactly one component record where the colour is white and the root pointer points to the root of the component. All nodes and white edges in this component point to this component record.

An example of how this looks is shown in Fig. 2. Notice that the colour of an edge $e$ is simply $e.cr.colour$ so the test in **MOVEEDGE** is trivial to implement. The implementation of **BREAK** is now:

9

Figure 2: A graph with component records.

**procedure** Break($v$)
    **if** $v.cr.colour = black$ **then**
        $r \leftarrow v$
    **else**
        $r \leftarrow v.cr.root$
        $v.cr.colour \leftarrow black$
        $v.cr.root \leftarrow -$
    **endif**
    **if** $r.Q \neq \emptyset$ **then**
        $u \leftarrow$ Rotate($r.Q$)
        **if** $u.cr.colour = black$ **then**
            $u.cr \leftarrow$ **new-component-record**($white, u$)
        **endif**
        $r.cr \leftarrow (u, r).cr \leftarrow u.cr$
    **endif**
    Zero($r$)
**end**.

From the discussion of the node copying method in Sect. 1 it should be clear that the above described data structure also applies to this method.

10

# 5 The analysis

**Theorem 3** *The player* **D** *strategy given in Sect. 3 achieves* $M = 2bd + 1$.
PROOF: A direct consequence of Lemma 1 and 2. □

**Lemma 1** *The player* **D** *strategy given in Sect. 3 achieves* $M \leq 2bd+1$.
PROOF: Let the first operation (either an ADDPEBBLE or MOVEEDGE operation) be performed at time 1, the next at time 2 and so on.

Assume that when the game starts all nodes are black and there are no pebbles on any node.

Fix an arbitrary node $v$ at an arbitrary time $t_{now}$. Let $t_{last}$ denote the last time before $t_{now}$ where $v$ was zeroed (if $v$ has never been zeroed let $t_{last}$ be 0). In the following we want to bound the number of pebbles placed on $v$ in the interval $]t_{last}, t_{now}[$. In this interval $v$ can not go from being black to being white because this would zero $v$.

Assume without loss of generality that $v$ is white at the end of time $t_{last}$, that at time $t_{break} \in ]t_{last}, t_{now}[$ a BREAK($C_v$) is performed and (therefore) at time $t_{now}$ $v$ is black (it is easy to see that all other cases are special cases of this case).

Note that the only time an ADDPEBBLE($v$) or MOVEEDGE($(v, u)$, $(v, w)$) operation can be performed is at time $t_{break}$ because these operations force the colour of $v$ to change. Therefore, $v$'s successors are the same in the interval $]t_{last}, t_{break}[$. Similarly for $]t_{break}, t_{now}[$.

We will handle each of the two intervals and the time $t_{break}$ separately. Let us first consider the interval $]t_{last}, t_{break}[$. Let $w$ be one of $v$'s successors in this interval. $w$ can at most be zeroed $b$ times before it will be blocked by a white edge from $v$ ($w$ can not change the colour without changing the colour of $v$), because after at most $b - 1$ ZERO($w$), $v$ will be the first element in $Q_w$.

So a successor of $v$ can be zeroed at most $bd$ times throughout the first interval which implies that at most $bd$ pebbles can be placed on $v$ during the first interval. For $]t_{break}, t_{now}[$ we can repeat the same argument so at most $bd$ pebbles will be placed on $b$ during this interval too.

11

We now just have to consider the operation at time $t_{break}$. The colour of $v$ changes so a $\textbf{BREAK}(C_v)$ is performed. There are three possible reasons for that: a) An $\textbf{ADDPEBBLE}(v)$ operation is performed, b) a $\textbf{MOVEEDGE}$ $((v,u),(v,w))$ is performed or c) one of the operations are performed on a node different from $v$. In a) and b) we first add a pebble to $v$ and then perform a $\textbf{BREAK}(C_v)$ operation and in c) we first add a pebble to another node in $C_v$ and then do $\textbf{BREAK}(C_v)$. The $\textbf{BREAK}$ operation can at most add one pebble to $v$ when we $\textbf{ZERO}$ the root of $C_v$ (because we do not allow multiple edges) so at most two pebbles can be added to $v$ at time $t_{break}$.

We have now shown that at time $t_{now}$ the number of pebbles on $v$ can at most be $2bd + 2$. This is nearly the promised result. To decrease this bound by one we have to analyse the effect of the operation performed at time $t_{break}$ more carefully.

What we prove is that when two pebbles are placed on $v$ at time $t_{break}$ then at most $bd - 1$ pebbles can be placed on $v$ throughout $]t_{break}, t_{now}[$. This follows if we can prove that there exists a successor of $v$ that cannot be zeroed more than $b - 1$ times in the interval $]t_{break}, t_{now}[$.

In the following let $r$ be the node that is zeroed at time $t_{break}$. We have the following cases to consider:

**i)** $\textbf{ADDPEBBLE}(v)$ and $\textbf{BREAK}(r)$ places a pebble on $v$. Now $r$ and one of its incoming edges are white. So $r$ can at most be zeroed $b - 1$ times before $(v, r)$ will become white and block further $\textbf{ZERO}(r)$ operations.

**ii)** $\textbf{MOVEEDGE}((v,u),(v,w))$ and $\textbf{ZERO}(r)$ places a pebble on $v$. Depending on the colour of $(v, u)$ we have two cases:

    **a)** $(v, u)$ is white. Therefore $u$ is white and $r \neq u$. Since we perform $\textbf{BREAK}(r)$ before we modify the pointers we have that $r \neq w$. So as in i) $r$ can at most be zeroed $b - 1$ times throughout $]t_{break}, t_{now}[$.

    **b)** $(v, u)$ is black. Since $\textbf{BREAK}$ is the last operation we do, the successors of $v$ will be the same until after $t_{now}$, so we can argue in the same way as i) and again get that $r$ at most can be zeroed $b - 1$ times throughout $]t_{break}, t_{now}[$.
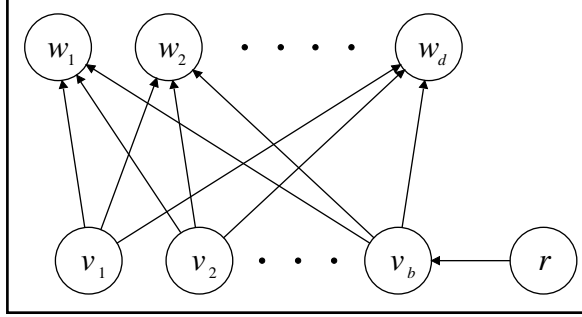

12

Figure 3: A graph which can force M to become $2bd + 1$.

We conclude that no node will ever have more than $2bd + 1$ pebbles. □

**Lemma 2** *The player* **D** *strategy given in Sect. 3 achieves* $M \geq 2bd+1$.

**Proof:** Let $G = (V, E)$ be the direct graph given by $V = \{r, v_1, \ldots, v_b, w_1, \ldots, w_d\}$ and $E = \{(r, v_b)\} \cup \{(v_i, w_j) | i \in \{1, \ldots, b\} \wedge j \in \{1, \ldots, d\}\}$. The graph is shown in Fig. 3. Initially all nodes in $V$ are black and all queues $Q_{w_i}$ contain the nodes $(v_1, \ldots, v_b)$. We will now force the number of pebbles on $v_b$ to become $2bd + 1$.

First place one pebble on $v_b$ — so that $v_b$ becomes white. Then place $2b - 1$ pebbles on each $w_j$. There will now be $bd$ pebbles on $v_b$ and all the edges $(v_b, w_j)$ are white. Place one new pebble on $v_b$ and place another $2b - 1$ pebbles on each $w_j$. Now there will be $2bd + 1$ pebbles on $v_b$. □

# 6   A simple locally adaptive strategy

In this section we present a simple strategy that is adaptive to the local in- and out-degree bounds of the nodes. It improves the bound achieved in [1]. The main drawback is that the strategy can not be implemented efficiently. In Sect. 7 we present an implementable strategy that is locally adaptive but does not achieve as good a bound on $M$.

Let $d_v$ denote the bound of the out-degree of $v$ and $b_v$ the bound of the in-degree. Define $M_v$ to be the best bound player **D** can guarantee on the number of pebbles on $v$. We would like to have that $M_v = f(b_v, d_v)$ for a monotonic function $f : N^2 \to N$.

13

The strategy is quite simple. To each node $v$ we associate a queue $Q_v$ containing the predecessors of $v$ and a special element ZERO. Each time the ZERO element reaches the front of the queue the node is zeroed.

> **The simple adaptive strategy**
>     **if** the **I**-move deletes $(v, u)$ and adds $(v, w)$ **then**
>         DELETE$(Q_u, v)$
>         ADD$(Q_w, v)$
>     **endif**
>     **while** $(v' \leftarrow \text{ROTATE}(Q_v)) \neq$ ZERO **do** $v \leftarrow v'$ **od**
>     ZERO$(v)$
> **end**.

Notice that the strategy does not use the values of $b_v$ and $d_v$ explicitly. This gives the strategy the nice property that we can allow $b_v$ and $d_v$ to change dynamically.

The best bound Dietz and Raman could prove for their strategy was that $M \leq 2b + 2d + O(\sqrt{b})$. The next theorem shows that the simple strategy above achieves a bound of $M_v = d_v + 2b_v$. If the graph is static the bound improves to $M_v = d_v + b_v$.

**Theorem 4** *For the simple adaptive strategy we have that $M_v = d_v + 2b_v$. In the static case this improves to $M_v = d_v + b_v$.*

PROOF: Each time we perform ADDPEBBLE$(v)$ or MOVEEDGE$((v, u), (v, w))$ we rotate $Q_v$. At most $b_v$ times can $Q_v$ be rotated without zeroing $v$. So between two ZERO$(v)$ operations at most $b_v$ MOVEEDGE operations can be performed on $v$ and therefore $v$ can at most have had $b_v + d_v$ different successors. Between two zeroings of a successor $w$ will $Q_v$ have been rotated because ROTATE$(Q_w)$ returned $v$, this is because the ZERO element is moved to the back of $Q_w$ when $w$ is being zeroed. So except for the first zeroing of $w$ all zeroings of $w$ will be preceded by a rotation of $Q_v$.

For each operation performed on $v$ we both place a pebble on $v$ and rotate $Q_v$. So the bound on the number of rotations of $Q_v$ gives the following bound on the number of pebbles that can be placed on $v$: $M_v \leq (d_v + b_v) + b_v$.
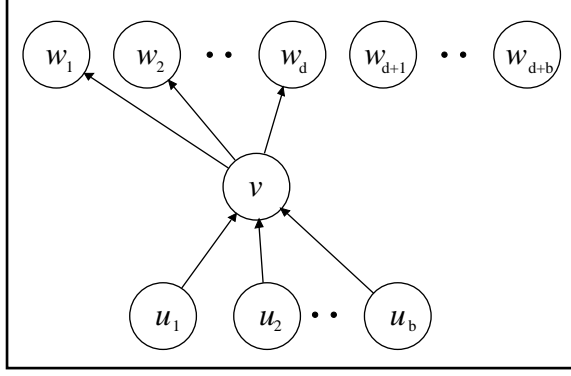

Figure 4: A graph which can force M to become $d_v + 2b_v$.

In the static case the number of different successors between two ZERO $(v)$ operations is $d_v$ so in the same way we get the bound $M_v \leq d_v + b_v$.

It is easy to construct an example that matches this upper bound. Let $G = (V, E)$ where

$$V = \{v, u_1, \ldots, u_{b_v}, w_1, \ldots, w_{d_v}, w_{d_v+1}, \ldots, w_{d_v+b_v}\} \text{ and}$$
$$E = \{(u_i, v) | i \in \{1, \ldots, b_v\}\} \cup \{(v, w_i) | i \in \{1, \ldots, d_v\}\}.$$

The graph is shown in Fig. 4.

At the beginning all nodes are black and the ZERO elements will be at the front of each of the nodes' queues. The sequence of operations which will force $P_v$ to become $d_v + 2b_v$ is the following: ADDPEBBLE on $v, w_1, \ldots, w_{d_v}$, followed by MOVEEDGE$((v, w_{i-1+d_v}), (v, w_{i+d_v}))$ and ADDPEBBLE$(w_{i+d_v})$ for $i = 1, \ldots, b_v$.

The matching example for the static case is constructed in a similar way. □

# 7   A locally adaptive data structure

We will now describe a strategy that is both implementable and locally adaptive. The data structure presented in Sect. 3 and Sect. 4 does *not* have this property, because when redoing the analysis with local degree constraints we get the following bound:

$$M_v = \sum_{w \in Out_v(]t_{last}, t_{break}[)} b_w + 1 + \sum_{w \in Out_v(]t_{break}, t_{now}[)} b_w.$$

15

The solution to this problem is to incorporate a ZERO element into each of the queues $Q_v$ as in Sect. 6 and then only zero a node when ROTATE returns this element. We now have the following BREAK operation:

```
procedure BREAK(C_v)
    r ← the root of C_v
    colour all nodes and edges in C_v black
    w ← ROTATE(Q_r)
    if w =ZERO then
        ZERO(r)
        w ← ROTATE(Q_r)
    endif
    if w ≠ZERO then
        colour r and (w, r) white
    endif
end.
```

The implementation is similar to the implementation of Sect. 4.

The next theorem shows that the number of pebbles on a node $v$ with this strategy will be bounded by $M_v = 2b_v d_v + 2b_v - 1$, so only nodes with large in-degree (or out-degree) can have many pebbles.

**Theorem 5** *The above strategy for player* **D** *achieves* $M_v = 2b_v d_v + 2b_v - 1$.

PROOF: The proof follows the same lines as in the proof of Theorem 3. A node $v$ can at most change its colour $2b_v - 1$ times between two zeroings. We then have that the number of ADDPEBBLE and MOVEEDGE operations performed on $v$ is at most $2b_v - 1$.

We have that the time interval between two ZERO($v$) operations is partitioned into $2b_v$ intervals and that $v$ changes its colour only on the boundary between two intervals. In each of the intervals each successor $w$ of $v$ can at most be zeroed once before it will be blocked by a white edge from $v$.

So when we restrict ourselves to the static case we have that each successor gets zeroed at most $2b_v$ times. Hence the successors of $v$ can at most place $2b_v d_v$ pebbles on $v$.

Each **AddPebble** operation places a pebble on $v$, so for the static case, the total number of pebbles on $v$ is bounded by $M_v = 2b_v d_v + 2b_v - 1$.

We now only have to show that a **MoveEdge**$((v, u), (v, w))$ operation does not affect this analysis. We have two cases to consider. If $u$ has been zeroed in the last interval then $u$ will either be blocked by a white edge from $v$ or $v$ appears before the **Zero** element in $Q_u$ and therefore none of the **Break** operations in **MoveEdge** can result in a **Zero**$(u)$. If $u$ has not been zeroed then it is allowed to place a pebble on $v$ in the **MoveEdge** operation. If the **Break** operation forces a **Zero**$(w)$ to place a pebble on $v$ then $w$ can not place a pebble on $v$ during the next time interval. So we can conclude that the analysis still holds.

The matching lower bound is given in the same way as in Theorem 4.
□

# 8 A lower bound

In this section we will only consider the static game.

Raman states in [3] that "the dependence on $d$ of $M$ appears to be an artifact of the proof (for the strategy of [1])". Theorem 6 shows that it is not an artifact of the proof, but that the value of $M$ always depends on the value of $b$ and $d$.

It is shown in [2] that in case of the amortised result we can get $M \leq b$, so in that game $M$ does **not** depend of $d$. So we have here a trade of between the amortised game and the worst case game.

**Theorem 6** *For $b \geq 1$ and all player $\mathbf{D}$ strategies we have:*

$$M \geq \max\{b + 1, \lfloor \alpha + \sqrt{2\alpha - 7/4} - 1/2 \rfloor, \left\lceil \frac{\log \frac{2}{3}d}{\log \log \frac{2}{3}d} - 1 \right\rceil\},$$

*where $\alpha = \min\{b, d\}$.*

**Proof:** Immediate consequence of Lemma 3 and 4 and Corollary 1.
□

**Lemma 3** *For $b, d \geq 1$ and all player $\mathbf{D}$ strategies we have $M \geq b + 1$.*

PROOF: We will play the game on a convergent tree with $l$ levels where each node has exactly $b$ incoming edges. The player **I** strategy is simple, it just places the pebbles on the root of the tree.

The root has to be zeroed at least once for each group of $M + 1$ ADD-DPEBBLE operations. So at least a fraction $\frac{1}{M+1}$ of the time will be spent on zeroing the root. At most $M$ pebbles can be placed on any internal node before the next ZERO operation on that node, because we do not perform ADDPEBBLE on internal nodes. So a node on level 1 has to be zeroed at least once for every $M$ ZERO operation on the root, so a node at level 1 has to be zeroed at least $\frac{1}{M(M+1)}$ of the time. By induction a node on level $i$ will be zeroed at least $\frac{1}{M^i(M+1)}$ of the time.

Because the number of nodes in each level of the tree increases by a factor $b$ we now have the following constraint on $M$:

$$\sum_{i=0}^{l} \frac{b^i}{M^i(M+1)} = \frac{1}{M+1} \sum_{i=0}^{l} \left(\frac{b}{M}\right)^i \leq 1.$$

So by letting $l \gg M$ we get that $M \geq b + 1$. If $d = 1$ Theorem 4 gives us that this is a tight bound. $\qquad \square$

**Lemma 4** *For $b, d \geq 1$ and all player **D** strategies we have:*

$$M \geq \left\lceil \frac{\log \frac{2}{3}d}{\log \log \frac{2}{3}d} - 1 \right\rceil.$$

PROOF: We will play the game on the following graph $G = (V, E)$ where $V = \{r, v_1, \ldots, v_d\}$ and $E = \{(r, v_1), \ldots, (r, v_d)\}$. The adversary strategy we will use for player **I** is to cyclically place pebbles on the subset of the $v_i$'s which have not been zeroed yet. The idea is that for each cycle at least a certain fraction of the nodes will not be zeroed.

We start by considering how many nodes can not be zeroed in one cycle. Let the number of nodes not zeroed at the beginning of the cycle be $n$. Each time one of the $v_i$'s is zeroed a pebble is placed on $r$, so out of $M + 1$ zeroings at least one will be a ZERO($r$). So we have that at least $\lfloor \frac{n}{M+1} \rfloor$ of the nodes are still not zeroed at the end of the cycle. So after $i$ cycles we have that the number of nodes not zeroed

18

is at least (the number of floors is $i$):

$$\left\lfloor \cdots \left\lfloor \left\lfloor \frac{d}{M+1} \right\rfloor \frac{1}{M+1} \right\rfloor \cdots \frac{1}{M+1} \right\rfloor .$$

By the definition of $M$, we know that all nodes will be zeroed after $M+1$ cycles, so we have the following equation (the number of floors is $M+1$):

$$\left\lfloor \cdots \left\lfloor \left\lfloor \frac{d}{M+1} \right\rfloor \frac{1}{M+1} \right\rfloor \cdots \frac{1}{M+1} \right\rfloor = 0.$$

Lemma 3 gives us that $M \geq 2$. By induction on the number of floors is it easy to show that by doing the calculations without any rounding, the resulting value is at most $3/2$ too big. A solution to the equation above will therefore also be a solution the the following inequality:

$$\frac{d}{(M+1)^{M+1}} \leq 3/2.$$

So the minimum solution of $M$ for this inequality will be a lower bound for $M$. It is easy to see that this minimum solution has to be at least $\frac{\log \frac{2}{3} d}{\log \log \frac{2}{3} d} - 1$. $\qquad \square$

**Lemma 5** *For all* **D** *strategies where* $b = d$ *we have:*

$$M \geq \lfloor b + \sqrt{2b - 7/4} - 1/2 \rfloor .$$

**PROOF:** For $b = d = 0$ the lemma is trivial. The case $b = d = 1$ is true by Lemma 3. In the following we assume $b = d \geq 2$.

Again, the idea is to use player **I** as an adversary that forces the number of pebbles to become large on at least one node.

The graph we will play the game on is a clique of size $b + 1$. For all nodes $u$ and $v$ both $(u, v)$ and $(v, u)$ will be edges of the graph and all nodes will have in- and out-degree $b$. Each ZERO operation of player **D** will remove all pebbles from a node of the graph and place one pebble on all the other nodes.

At a time given $P_0, P_1, \ldots, P_b$ will denote the number of pebbles on each of the $b + 1$ nodes — in increasing order, so $P_b$ will denote the number of pebbles on the node with the largest number of pebbles.
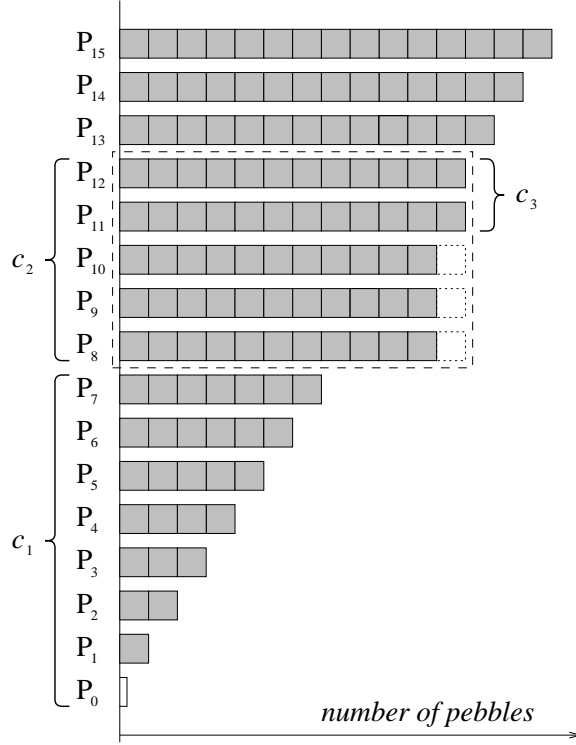

Figure 5: The adversary's strategy.

From a certain time on we will satisfy the following invariants. We let $c_1, c_2$ and $c_3$ denote constants characterising the adversary's strategy.

$$
\begin{aligned}
I_1 : & \qquad i \leq j \Rightarrow P_i \leq P_j, \\
I_2 : & \qquad P_i \geq i, \\
I_3 : & \begin{cases} P_{c_1+c_2-i} \geq c_1 + c_2 - 1 & \text{for } 1 \leq i \leq c_3, \\ P_{c_1+c_2-i} \geq c_1 + c_2 - 2 & \text{for } c_3 < i \leq c_2, \end{cases} \\
I_4 : & \quad 1 \leq c_3 \leq c_2 \quad \text{and} \quad c_1 + c_2 \leq b + 1.
\end{aligned}
$$

$I_1$ is satisfied per definition. $I_2$ is not satisfied initially but after the first $b$ ZERO's will be satisfied. This is easily seen. The nodes that have not been zeroed will have at least $b$ pebbles and the nodes that have been zeroed can be ordered according to the last time they were zeroed. A node followed by $i$ nodes in this order will have at least $i$ pebbles because each of the following (at least) $i$ zeroings will place a pebble on the node.

We can now satisfy $I_3$ and $I_4$ by setting $c_1 = c_2 = c_3 = 1$ so now we have that all the four invariants are satisfied after the first $b$ ZERO

20

operations.

Figure 5 illustrates the relationship between $c_1, c_2$ and $c_3$ and the number of pebbles on the nodes. The figure only shows the pebbles which are guaranteed to be on the nodes by the invariants. The idea is to build a *block* of nodes which all have the same number of pebbles. These nodes are shown as a dashed box in Fig. 5. The moves of player **I** and **D** affect this box. A player **I** move will increase the block size whereas a player **D** move will push the block upwards. In the following we will show how large the block can be forced to be.

We will first consider an ADDPEBBLE operation. If $c_3 < c_2$ we know that on node $c_1 + c_2 - c_3 - 1$ (in the current ordering) there are at least $c_1 + c_2 - 2$ pebbles so by placing a pebble on the node $c_1 + c_2 - c_3 - 1$ we can increase $c_3$ by one and still satisfy the invariants $I_1, \ldots, I_4$. There are three cases to consider. If the node $c_1 + c_2 - c_3 - 1$ already has $c_1 + c_2 - 1$ pebbles we increase $c_3$ by one and try to place the pebble on another node. If $c_3 = c_2$ and $c_1 + c_2 < b + 1$ we can increase $c_2$ by one and set $c_3 = 1$ and then try to place the pebble on another node. If we have that $c_2 = c_3$ and $c_1 + c_2 = b + 1$ we just place the pebble on an arbitrary node — because the block has reached its maximum size.

Whenever player **D** does a ZERO operation we can easily maintain the invariant by just increasing $c_1$ by one — as long as $c_1 + c_2 < b + 1$. Here we have three cases to consider. Let $i$ denote the number of the node that player **D** zeroes. We will only consider the case when $c_1 \le i < c_1 + c_2$, the cases $0 \le i < c_1$ and $c_1 + c_2 \le i \le b$ are treated in a similar way. The values of the $P$s after the ZERO operation are: $P'_0 = 0, P'_1 = P_0 + 1, \ldots, P'_i = P_{i-1} + 1, P'_{i+1} = P_{i+1} + 1, \ldots, P'_b = P_b + 1$. So because $I_2$ and $I_3$ were satisfied before the ZERO operation it follows that when we increase $c_1$ by one the invariant will still be satisfied after the ZERO operation.

We will now see how large the value of $c_2$ can become before $c_1 + c_2 = b + 1$. We will allow the last move to be a player **I** move.

We let $x$ denote the maximum value of $c_2$ when $c_1 + c_2 = b + 1$. At this point we have that $c_1 = b + 1 - x$. Initially we have that $c_1 = 1$. Each ZERO operation can at most increase $c_1$ by one so the maximum number of ADDPEBBLE operations we can perform is $1 + ((b + 1 - x) - 1) =$

$b + 1 - x$.

It is easily seen that the worst case number of pebbles we have to add to bring $c_2$ up to $x$ is $1 + \sum_{i=2}^{x-1} (i - 1)$ — because it is enough to have two pebbles in the last column of the block when we are finished.

So the size of $x \geq 0$ is now constrained by:

$$1 + \sum_{i=2}^{x-1} (i - 1) \leq b + 1 - x.$$

Which gives us that:

$$\frac{(x - 2)(x - 1)}{2} \leq b - x,$$
$$x^2 - x + (2 - 2b) \leq 0,$$

and therefore $x \geq \lfloor 1/2 + \sqrt{2b - 7/4} \rfloor$. Let $i \in \{0, 1, \ldots, x - 1\}$ denote the number of ZERO operations after the block has reached the top. By placing the pebbles on node $b - 1$ it is easy to see that the following invariants will be satisfied ($I_3$ and $I_4$ will not be satisfied any longer):

$$I_5 : \quad P_b \geq b + i,$$
$$I_6 : P_{b-j} \geq b + i - 1 \quad \text{for } j = 1, \ldots, x - i - 1.$$

So after the next $x - 1$ zeroings we see that $P_b \geq b + (x - 1)$ which gives the stated result. $\qquad \square$

**Corollary 1** *For all* **D** *strategies we have* $M \geq \lfloor \alpha + \sqrt{2\alpha - 7/4} - 1/2 \rfloor$ *where* $\alpha = min\{b, d\}$.

# 9    Conclusion

In the preceding sections we have shown that it is possible to implement partially persistent bounded in-degree (and out-degree) data structures where each access and update step can be done in worst case constant time. This improves the best previously known technique which used amortised constant time per update step.

It is a further consequence of our result that we can support the operation to delete the current version and go back to the previous version in constant time. We just have to store all our modifications of the data structure on a stack so that we can backtrack all our changes of the data structure.

# 10 Open problems

The following list states open problems concerning the dynamic two player game.

- Is it possible to show a general lower bound for $M$ which shows how $M$ depends on $b$ and $d$?

- Do better (locally adaptive) strategies exist?

- Do implementable strategies for player **D** exist where $M \in O(b + d)$?
