ABSTRACT
Constrained skyline queries retrieve all points that optimize some user’s preferences subject to orthogonal range constraints, but at significant computational cost. This paper is the first to propose caching to improve constrained skyline query response time. Because arbitrary range constraints are unlikely to match a cached query exactly, our proposed method identifies and exploits similar cached queries to reduce the computational overhead of subsequent ones.

We consider interactive users posting a string of similar queries and show how these can be classified into four cases based on how they overlap cached queries. For each we present a specialized solution. For the general case of independent users, we introduce the Missing Points Region (MPR), that minimizes disk reads, and an approximation of the MPR. An extensive experimental evaluation reveals that the querying for an (approximate) MPR drastically reduces both fetch times and skyline computation.

1. INTRODUCTION
Constrained Skyline A constrained skyline query [3] is an effective way of filtering a constrained dataset to points that express all optimal trade-offs of the dataset’s attributes. For example, if searching for cheap 3+ star hotels near a conference venue, one hotel is said to dominate another if it is at least as highly rated, well priced and near as the latter, yet strictly better than the other hotel on at least one of these metrics. The constrained skyline is the set of points that satisfy the given constraints and are not dominated by any others that satisfy the constraints. In practice, the constraints are critical in allowing users to determine the skyline on the data relevant to them. E.g. average income earners may not be interested in luxury hotels nor backpacker hostels, so a non-constrained skyline cannot capture their preferences. Constraints reduce the input size, yet, paradoxically, makes computing the skyline quite challenging, because, unlike an unconstrained skyline which can be pre-materialized, the skyline points are unpredictable.

The naive approach, presented in [3], is to execute a range query to fetch points satisfying the constraints, and then compute the skyline over those points using an efficient skyline algorithm (e.g., [8, 16, 23]). This has the advantage of simplicity, but the performance is highly sensitive to the selectivity of the range query. The best known technique is the I/O-optimal BBS algorithm [19], which uses an R-tree index and a heap-based priority queue to guide the search for skyline points, while pruning paths in an R-Tree if outside the constraints. In this paper, we outperform BBS by reusing partial query solutions.

Caching A fair assumption is that many users will pose constrained skyline queries on the same dataset. Where users have similar needs, the constraint regions likely overlap. For example, young backpackers will all typically search with price constraints that match a cheap budget, producing similar queries. Business travellers, conversely, may be more concerned with location than price; a distinct set of similar queries.

Figure 1: Small constraint changes have large impacts on skylines

Additionally, an iterative, exploratory query-refine cycle is common in search tasks [18], where a user issues a query, observes the results, and then adjusts constraints to manipulate the results. Hence, even a single user can produce strings of highly similar queries, each with distinct skylines [6, 17].

So, this paper addresses a natural question: how can the results of a constrained skyline query be reused to speed up subsequent, similar ones? In contrast to existing techniques (e.g., [3, 19]), we can obtain significant speed-up by decomposing a range query into disjoint smaller ones, and discarding those that a previous cached query result implies are unnecessary, hence reading fewer data points than the isolated query necessitates.

Challenges Despite the apparent simplicity of overlapping two range queries to compare results, caching constrained skylines is deceptively challenging. Unlike previous research on caching (sub-space) skyline queries [2, 14, 20] where constraints are not considered, cache hits with exact matching constraints are quite unlikely, especially for real-valued and high-dimensional data. Therefore,
we investigate how to infer partial skyline solutions from overlapping, rather than matching, query constraints, which would yield a low cache hit rate.

This, however, introduces a new challenge, because small changes to constraints can have a profound impact on the skyline [6]. For example, Figure 1 shows an “old” (solid) and “new” (dashed) constrained skyline query on a toy hotel example, where the minor increase to the Price-constraint from the “old” to the “new” query is enough to eliminate a skyline point (minus), which promotes three previously dominated points into the skyline (plus). To address this challenge, we introduce the notion of stability which characterizes how solution points will be shared among old and new queries. Even in difficult, unstable cases, we show how a previous query’s solution points, even when not satisfying the current constraints, can prune the current search range.

Finally, dimensionality poses a natural challenge for caching constrained skylines by increasing the pruning complexity (as we show in Section 5.3). Therefore, we present an effective approximation technique that balances the number and selectivity of small range queries. As a result, we can outperform baseline and the I/O-optimal BBS algorithms by several factors, and scale elegantly with increasing workloads.

Contributions Despite the cost of constrained skylines, this paper is the first to investigate how caching can drastically improve their running time. After reviewing related work (Section 2) we introduce the problem formally (Section 3) and make the following novel contributions (Sections 4-6) before concluding the paper (Section 8).

- For the exploratory use case, in which subsequent queries differ only by one constraint, we present a case-by-case breakdown of the four possible overlap relationships, along with how to compute the constrained skyline for each (Section 4);
- For the general case of arbitrary constraint overlap, we introduce an algorithm to compute the Missing Points Region (MPR), which is the minimal region that must be queried from disk. We also introduce an Approximate MPR (aMPR), sacrificing minimality for fewer independent range queries (Section 5);
- We introduce a caching algorithm, Cache-Based Constrained Skyline (CBCS) that handles cache searching, management and use based on the earlier analysis (Section 6); and
- We conduct an extensive experimental evaluation of our method to show how our caching yields superior efficiency for related queries relative to baselines and state-of-the-art (Section 7).

2. RELATED WORK

Constrained skylines The skyline operator [3] was introduced along with a straightforward extension to constrained skyline queries that first retrieves all data satisfying the constraints, and then applies any skyline algorithm (e.g., [7,8,16,23]). Subsequently, the R-tree-based method BBS [19] supports constraints by pruning paths in the R-tree if they are outside the constraint region. BBS is I/O-optimal and state-of-the-art when not using caching. We include it in our empirical study (Sect. 7).

For arbitrary subsets of dimensions, known as subspaces, [10] partitions data and queries vertically onto several low-dimensional R-trees. Without subspaces, their approach is essentially a constraint-based version of the NN method [15], shown in [19] to be inferior to BBS for constrained skylines. [9] study distributed constrained skylines where distributed local skylines are merged into a global result. Efficiency gains come from computing independent local skylines at data sites in parallel, meaning that a non-distributed application is equivalent to computing the constrained skyline naively. [1] study constrained subspace skylines in a horizontally partitioned P2P environment. Constrained subspace skylines are computed in order of potential dominance on each node, avoiding those pruned by earlier nodes. It suffers the same limitations as [9]. [22] study continuous constrained skyline queries for streams, determining areas that could influence the current skyline. The problem is different from ours, namely maintenance of fixed constrained skylines for dynamic data, rather than dynamic constraints. [11] study query optimization of Semi-skylines, which use partial order preferences. If applied only to traditional constraints, the method corresponds to recomputation from scratch for any change in constraints. [4] estimates the cardinality of (constrained) skylines in a DBMS and can be used to assess which skyline algorithm to apply in the naive approach.

Caching skylines [12] and [5] study caching of subspace skylines in a P2P setting using local caches with a superpeer network and a centralized index, respectively. Neither support constrained skylines. [2] study caching of subspace skylines, where results are cached directly and used to answer queries in related subspaces. [14] caches partial-order domain user preferences to process queries with similar user preferences. [20] caches dynamic skylines, where domination is based on the distance to a query. None of them consider constraints and thus suffer from the same issues as [12] and [5].

In conclusion, existing constrained skylines algorithms demand recomputation from scratch if constraints differ even slightly. Also, existing caching approaches only support identical constraints, which is unlikely to occur in practice, especially when considering, e.g., exploratory search scenarios, real-valued data, multiple users and several dimensions. In this work, we limit the number of points read and dominance tests performed, by reusing cached results on similar constraints.

3. PRELIMINARIES

Let $S$ be a set of data points over an ordered set of numerical dimensions $D$, where the value of $s \in S$ in dimension $i \in D$ is denoted $s[i]$. A set of constraints, $C = \{ C[i] \}$, is a pair of points indicating the minimum value, $C[i]$, and the maximum value, $\overline{C}[i]$, for each dimension $i \in D$. A constraint region, $R_C$, is the set of all possible points satisfying constraints $C$:

$$R_C = \left\{ p \in R^{|D|} \mid \forall i \in D : C[i] \leq p[i] \leq \overline{C}[i] \right\}.$$

Observe that $R_C$ describes a $|D|$-dimensional hyper-rectangle, like the rectangles in Figure 1. Similarly, the constrained data, $S_C$, is the set of data points that satisfy constraints $C$:

$$S_C = \{ s \in S \mid \forall i \in D : C[i] \leq s[i] \leq \overline{C}[i] \}.$$

We note the following properties relating constraint regions and constrained data:

1. Given constraints $C$, the set of points $S_C$ satisfying constraints $C$ form a (possibly empty) subset of the set of points in the region $R_C$ described by $C$: $S_C \subseteq R_C$.

$$\text{3. PRELIMINARIES}$$

$$\text{Let } S \text{ be a set of data points over an ordered set of numerical dimensions } D, \text{ where the value of } s \in S \text{ in dimension } i \in D \text{ is denoted } s[i]. \text{ A set of constraints, } C = \{ C[i] \}, \text{ is a pair of points indicating the minimum value, } C[i], \text{ and the maximum value, } \overline{C}[i], \text{ for each dimension } i \in D. \text{ A constraint region, } R_C, \text{ is the set of all possible points satisfying constraints } C:$$

$$R_C = \left\{ p \in R^{|D|} \mid \forall i \in D : C[i] \leq p[i] \leq \overline{C}[i] \right\}.$$
In this paper we study how to efficiently answer constrained skyline queries (Def. 1) given $S$ and $C$, if an in-memory cache (Def. 3) is available. The skyline is defined through the concept of dominance [3]: a point $s \in S$ (or, analogously, $s \in R$) dominates another point $t \in S$, denoted $s \succ t$, iff $\exists i \in D: s[i] < t[i]$ and $\forall j \in D, s[j] \leq t[j].$ In order words, $s$ is at least as small as $t$ on every attribute, and strictly smaller on at least one.

The conventional skyline of $S$, denoted $Sky(S)$, is the subset of points not dominated by any other points in $S$:

$$Sky(S) = \{ s \in S \mid \nexists t \in S : t \succ s \}.$$  

These are exclusively those points that minimize some linear function over the dataset’s dimensions. Figure 2 illustrates the skyline with black points for our running hotel example.

The constrained skyline is the set of points that satisfy the constraints while not being dominated by any other points that also satisfy the constraints (Definition 1). Equivalently, it is the skyline over input $S_C$.

**Definition 1** (Constrained skyline [3, 19]).

Given $S, C$, the constrained skyline, denoted $Sky(S, C)$, is:

$$Sky(S, C) = Sky(S_C) = \{ s \in S_C \mid \nexists t \in S_C : t \succ s \}.$$  

Figure 2 also illustrates a constrained skyline as the set of gray points in the rectangle spanned by constraints $C = (C_i, C_t)$. Note here again that the constrained skyline can be very different from the conventional skyline (black points).

Every point $s \in S$ (or $s \in R$) has a dominance region [10], denoted $DR(s)$, which is the hyper-rectangular region in which any point $p$ is dominated by $s$ (Definition 2).

1 Assumed without loss of generality: a preference for maximization can be handled by multiplying an attribute by -1.

**Definition 2** (Dominance region [10]).

For point $s \in S$, the dominance region is defined as:

$$DR(s) = \{ p \in R \mid s \succ p \}.$$  

For any $s \in S$, $DR(s) \cap Sky(S) = \emptyset$; so dominance regions help detect subsets of points that need not be fetched from disk. In the presence of constraints $C$, each point $s$ also induces a constrained dominance region, denoted $DR(s, C)$, which is the portion of $DR(s)$ that satisfies $C$. The gray rectangles in Figure 2 illustrate $DR(t)$ for a conventional skyline point $S$ and $DR(s, C)$ for a constrained skyline point.

Lastly, our objective is to resolve constrained skyline queries using in-memory constrained skyline cache items. A cache item (Definition 3) is a 3-tuple consisting of an earlier queried set of constraints, the resultant constrained skyline, and the skyline’s minimum bounding rectangle (MBR).

**Definition 3** (Constrained skyline cache).

Given $S, C'$, and an in-memory cache $\{I_1, \ldots, I_n\}$, utilize a cache item $I'_i$, to compute $Sky(S, C')$ without fetching all of $S_C$.

With the notation in place (and summarized in Table 1), the problem studied in this paper can now be stated as follows:

**Problem Statement** (Cache-based constrained skyline).

Given $S, C'$, and an in-memory cache $\{I_1, \ldots, I_n\}$, utilize a cache item $I'_i$, to compute $Sky(S, C')$ without fetching all of $S_C$.

![Figure 2: Illustration of a skyline (black points) and constrained skyline (grey points inside the rectangle) on our running example. Also shown are dominance regions (solid gray rectangles).](image-url)
4.1 Skyline stability

Clearly, a cache item for Sky(S, C) indicates which points from S are in Sky(S, C). More importantly, it also implies which points from S_C are not in Sky(S, C). Stability (Definition 4) captures this insight relative to new constraints, C'.

Definition 4 (Constrained skyline stability). We say that Sky(S, C) is stable relative to C' iff:

s ∈ Sky(S, C') ⇒ (s ∈ S_C) ∨ (s ∈ Sky(S, C))

In other words, Sky(S, C) is stable relative to C' if points from S_C not in Sky(S, C) are also not in Sky(S, C'). Otherwise, we call Sky(S, C) unstable relative to C'. We observe in Theorem 1 that stability is guaranteed when, for all i ∈ D, C'_i ≥ C'_i (or, trivially, when constraints do not overlap).

Theorem 1 (Guaranteed stability). Sky(S, C) is guaranteed to be stable relative to C' iff:

(∀i ∈ D: C'_i ≤ C'_i) ∨
(∃i ∈ D: C'_i > C'_i ∨ C'_i < C'_i)

The full proof of Theorem 1 is in Appendix 9, but the intuition is that new constraints can only invalidate the skyline if they shrink the constraint region, removing skyline points and thereby their dominance region influence on the skyline result. Stability is guaranteed since no point s ∈ S_C dominated by removed point t ∈ Sky(S, C) can satisfy an upper constraint that t does not satisfy.

From Definition 4 and Theorem 1 come two natural consequences. First, for stable cases, we need only fetch points in the new part of the constraint region that did not satisfy the old constraints (Corollary 1). Second, a skyline result is unstable if and only if an "old" skyline point s ∈ Sky(S, C) is outside the "new" constraints C', and it dominated points that still satisfy the new constraints (Corollary 2).

Corollary 1. If Sky(S, C) is stable relative to C' then:

∀s ∈ Sky(S, C'): (s ∈ Sky(S, C)) ∨ (s ∈ Sky(S, C'))

Corollary 2. Sky(S, C) is unstable relative to C' iff:

∃s ∈ Sky(S, C): s ∉ Sky(S, C') ∧
∃t ∈ Sky(S, C): t ∉ Sky(S, C') ∧
∃u ∈ (Sky(S, C) ∩ Sky(S, C')): u > s

4.2 Incremental constraint changes

With the theory of stability in place, we show how any incremental change can be solved with minimum points read. For each of four possible cases, we prove the correctness and minimality (proofs in Appendix 9) of our solution and illustrate the intuition of the ideas by example/illustration.

Figures 3a-3d show the four cases for incremental changes of constraints C (the solid rectangle), one dimension at a time: (a) decreasing a lower constraint, (b) decreasing an upper constraint, (c) increasing an upper constraint and (d) increasing a lower constraint. Note that we always have only these four cases, regardless of dimensionality. The initial constraints C = (C, C') and new constraints C', as well as the change ∆C from C to C' are displayed in each figure. For each case, the part of S_C that we fetch is enclosed in the gray region. Note that while the illustrated gray regions are all rectangular, this only holds for |D| = 2 as we will show in Section 5.3.

Case (a): Decreasing a lower constraint (Fig. 3a) From Theorem 1, Sky(S, C) is stable relative to C', and from Corollary 1 all new skyline points lie in ∆C. Instead of fetching all of S_C, we can fetch just the points in (R_C' \ R_C). Further pruning is not possible: no points in Sky(S, C) dominate any part of ∆C.

Theorem 2 (Case (a) solution). If C' ≤ C, then:

Sky(S, C') = Sky(S, C) ∪ S_C ∩ C'

In the example (Fig. 3a), a, b and c are fetched from the database with a, c as new skyline points (illustrated by a plus sign), while existing d, f are dominated by a and c under constraints C' (illustrated by a minus sign). The final skyline is a, c, e, i. Without the cached Sky(S, C), we must read 12 points, a-d, from disk.

Case (b): Decreasing an upper constraint (Fig. 3b) Again, from Theorem 1, Sky(S, C) is stable wrt C'. From Corollary 1 the skyline points in Sky(S, C') are in Sky(S, C) or in ∆C. Since R_C' is enclosed in R_C, we need simply remove the previous skyline points not satisfying the new constraints.
Theorem 3 (Case (b) solution).

If \( C' = C \), \( \exists t: C'[i] > C[i], \forall j \in D \setminus \{i\}: C'[j] = C[j] \), then:

\[
\text{Sky}(S, C') = \text{Sky}(S, C) \cap S_{C'}
\]

In this example (Fig. 3b), only 1 falls outside the new constraints and is simply removed to obtain the new skyline.

Case (c): Increasing an upper constraint (Fig. 3c) As before, \( \text{Sky}(S, C) \) is stable relative to \( C' \) (Theorem 1), and new skyline points in \( \text{Sky}(S, C') \) are in \( \text{Sky}(S, C) \) or in \( \Delta C \) (Cor. 1). Unlike before, however, we use the dominance regions of points in \( \text{Sky}(S, C') \) to further prune parts of \( \Delta C \):

Theorem 4 (Case (c) solution).

If \( C' = C \), \( \exists t: C'[i] > C[i], \forall j \in D \setminus \{i\}: C'[j] = C[j] \), then:

\[
\text{Sky}(S, C') = \text{Sky}(\text{Sky}(S, C) \cup \{s \in S_{AC} \mid \exists t \in \text{Sky}(S, C): t > s\}, C')
\]

We thus prune \( S_{AC} \) such that we only read \( ((\text{Sky}(S, C) \setminus S_{C}) \setminus \{s \in S_{AC} \mid \exists t \in \text{Sky}(S, C): t > s\}) \). In the example (Fig. 3c), \( R_{C'} \) contains 18 points, the logic of Case (a) reduces it to 9 points, and we eventually fetch only 2 points, \( m \) and \( n \).

Case (d): Increasing a lower constraint (Fig. 3d) Unlike Cases (a)-(c), \( \text{Sky}(S, C) \) is not stable relative to \( C' \). Despite this instability, we can use the old skyline result by determining invalidated parts of the cache item and reevaluate these under constraints \( C' \). Using what is left of \( \text{Sky}(S, C) \) within the queried constraints \( C' \) we prune regions before reading from disk. Since no two skyline points dominate each other (Def. 1), the remaining part of \( \text{Sky}(S, C) \) is not invalidated:

Theorem 5 (Case (d) solution).

If \( C' = C \), \( \exists t: C'[i] > C[i], \forall j \in D \setminus \{i\}: C'[j] = C[j] \), then:

\[
\text{Sky}(S, C') = \text{Sky}(\text{Sky}(S, C) \cap S_{C'} \cup \{s \in S_{AC} \mid \exists t \in \text{Sky}(S, C): t > s\}, C')
\]

Thus, we avoid reading \( (S_{C} \cap S_{C'}) \) fully, and retrieve only \( ((S_{C} \cap S_{C'}) \setminus \{s \in (S_{C} \cap S_{C'}) \mid \exists t \in \text{Sky}(S, C) \cap S_{AC}: t > s\} \cup \{s \in S_{AC} \mid t > s\}, C') \)

In the example (Fig. 3d) instead of 7 points, we only fetch 6. Throughout all examples, we save the latency of fetching unnecessary points, and the cost of conducting dominance tests over an otherwise larger input.

5. ARBITRARY CONSTRAINT CHANGES

In this section, we build on the intuition from Section 4 to handle the general case where the number of constraint changes is arbitrary. We first generalize the gray regions of the previous section into the Missing Points Region (MPR), the minimal area that must be fetched (Section 5.1), and introduce an efficient algorithm to compute it (Section 5.2). We then illustrate how the MPR grows arbitrarily complex with dataset dimensionality (Section 5.3) and introduce an effective approximation to reduce that complexity (Section 5.4).

5.1 The Missing Points Region

Given constraints \( C \) and \( C' \), the Missing Points Region (the gray rectangles in Figure 3) is the minimum, possibly disjoint, region of points for which neither \( C' \) nor \( \text{Sky}(S, C) \) can be used to infer said points’ inclusion/exclusion in \( \text{Sky}(S, C') \). It is comprised of those parts of \( R_{C'} \) that do not overlap the dominance region of any point \( s \in \text{Sky}(S, C) \), lies outside \( R_{C} \), or, in unstable cases, where \( \exists t (\text{Sky}(S, C) \cap (S_{C} \setminus S_{C'})), s \in (S_{C} \cap S_{C'}): t > s \) (Definition 5).

Definition 5. (Missing Points Region)

Given \( \text{Sky}(S, C), C' \), the Missing Points Region, MPR, is:

\[
\text{MPR} = \{ p \in R_{C'} \mid (p \in R_{C} \cap (R_{C} \setminus R_{C'})) \lor \exists t \in \text{Sky}(S, C) \cap (R_{C} \setminus R_{C'}); p \in DR(t, C) \land \exists u \in \text{Sky}(S, C) \cap R_{C'} \}
\]

The MPR is both complete and minimal in the sense that, with knowledge only of \( \text{Sky}(S, C) \) and \( C' \), any point in MPR could be in \( \text{Sky}(S, C') \) (Theorems 6 and 7, respectively).

Theorem 6. (Completeness) Given \( \text{Sky}(S, C), C' \), where \( R_{C} \cap R_{C'} \neq \emptyset \), we have:

\[
\text{Sky}(S, C', C'') = \text{Sky}((\text{Sky}(S, C), C') \cap (\text{MPR} \cap \Delta C))
\]

The full proof of Theorem 6 is in Appendix 9, but the intuition is that there are only two ways in which points can be missing: (1) Expansion of \( C \) and (2) Invalidation of \( C \). All expanded and invalidated areas are fetched unless guaranteed excluded by known points from \( \text{Sky}(S, C) \). The remaining non-invalidated regions of \( S_{C} \) remain stable.

Theorem 7. (Minimality) Given only \( \text{Sky}(S, C), C' \), where \( S_{C} \setminus S_{C'} \neq \emptyset \), any point in \( \text{MPR} \cap S_{C'} \) could be in \( \text{Sky}(S, C') \).

The full proof of Theorem 7 is also in Appendix 9, but the intuition is that by definition no known point outside MPR can dominate a point inside MPR, only points inside MPR can dominate each other. Thus to minimize MPR further, we must know the contents of MPR, which we cannot do without fetching the points in MPR.

5.2 Computing the MPR

We present our algorithm to compute the MPR, which, per Theorem 7 is used to minimize points fetched. Our general approach is to start with the hyper-rectangle \( (C', \mathcal{C}) \) and continually split it using \( C \) and \( \text{Sky}(S, C) \) into sub-hyper-rectangles such that many of them can be immediately discarded. At the end, we are left with a set \( \mathcal{H} \) of disjoint, axis-orthogonal hyper-rectangles (i.e., range queries) covering the exact region of the MPR.

The advantage of this approach is three-fold: 1) it calculates the MPR in a form (set of range queries) that can be queried directly; 2) the primary operation, splitting axis-orthogonal hyper-rectangles with axis-orthogonal hyperplanes, is simple and efficient; and 3) the continual discarding of hyper-rectangles controls \( \mathcal{H} \), important because the algorithm runs \( O(|H| \cdot |\text{Sky}(S, C)| \cdot |D|) \).

In general, the algorithm consists of three steps: taking regions unknown to the cache; adding invalidated regions (in the unstable case); and removing the dominance regions of cached skyline points. Algorithm 1 presents the pseudocode (with unstable case handling omitted due to space constraints).

Lines 2–10 calculate the overlap region, \( o \equiv \langle q_{l}, q_{r} \rangle \), the area satisfying both \( C \) and \( C' \), by splitting the range into sections based on the boundary of the cache item for each dimension, eventually yielding the overlap region and disjoint regions around it. In the stable case \( o \) can simply be removed (Line 11); we discuss the unstable case later. Line 12 discards any hyper-rectangle \( h \equiv \langle l, r \rangle \) for which \( h_{l} = 7 \), since \( h \) is clearly in a dominance region. After Line 12, the first of the three steps is complete, and \( \mathcal{H} \) captures
Algorithm 1 MPR - Stable Skyline(S,C) relative to C'

Input: I = \{Sky(S,C), MBR, C\}, C'

Output: A set of range queries
1: H ← Set of hyperrectangles (Initially only R_{C'})
2: for all dimensions i ∈ D do
3: for all hyperrectangles r ∈ H do
4: Copy r to r_{<r}, r_{=} and r_{>r}
5: Add to r_{<r} constraint p[i] ≤ C[i]
6: Add to r_{=} constraints C[i] ≤ p[i] ≤ C[i]
7: Add to r_{>r} constraint C[i] ≤ p[i]
8: Del r from H and, if satisfiable, add r_{<r}, r_{=} and r_{>r}
9: end for
10: end for
11: Remove overlap region o = (R_{C} ∩ R_{C'}) from H
12: Remove h ∈ H where h = o
13: for all skyline points u ∈ Sky(S,C) do
14: for all dimensions i ∈ D do
15: for all r ∈ H not marked with u and DR(u) ∩ r ≠ Ø do
16: Copy r to r_{<r} and r_{>r}
17: Add to r_{<r} constraint p[i] ≤ u[i]
18: Add to r_{=} constraint p[i] ≥ u[i]
19: Mark r_{<r} with u and flag r_{>r} as dominated
20: if r_{<r} and r_{>r} are satisfiable then
21: Remove r and add r_{<r} and r_{>r} to H
22: end if
23: end for
24: end for
25: Discard all r ∈ H flagged as dominated
26: end for
27: Return H as range queries

all regions outside the cache in which missing skyline points could exist. Lines 13–26 conduct the third step, looping through each dimension of each skyline point to split the remaining h ∈ H. With each split we flag one part of h as processed by the current point and the other as being dominated. The dominated part can be discarded on Line 25, and the flagging of the other part avoids unnecessarily resplitting it. For simplicity of presentation, we assumed no points lie on a range query border. This assumption can be removed by setting either inequality to be strict on Lines 5–7, 16–21. Finally, the unstable case is solved similarly; we simply run a slight modification of Algorithm 1 as a preprocessing step to determine the invalidated regions, and add those to the set H between Lines 11 and 12. The modification is an inversion of the logic: we want to process (not discard) the overlap region, o, and discard (not keep) the rest. We want to keep (not discard) that which overlaps dominate regions and discard (not keep) the rest. This inverted logic produces a quite small set H' that exactly represents the unstable, invalidation region. By adding H' to H after Line 11, it is then reduced exactly the same as the stable part of the MPR.

5.3 Approximating the MPR

In 2D cases (such as Figures 3 and 4a), the MPR (gray region) of the changed constraints (the dashed lines) relative to the old skyline (solid black points) is a simple rectangle. However, each new dimension adds complexity. By considering a third dimension (Figure 4b), the same 8 points and set of constraints produces an MPR consisting of 8 rectangular regions (the hollow part on top). This complexity grows for each distinct z-coordinate because the dominance region of each skyline point is (logically) subtracted from the MPR.

Therefore, we introduce the Approximate MPR (aMPR). The aMPR is a conservative approximation of the MPR which produces no false negatives by simplifying the structure of MPR, thus creating a structure that decomposes into fewer, but larger, disjoint range queries. This in turn produces a superset of the points in MPR, thus guaranteeing completeness at a lower processing cost. The aMPR represents a middle ground approach between the minimum reads of the MPR and the maximum points read of the naive approach in [3].

The aMPR arises from a simple observation. As mentioned earlier, the complexity of the MPR comes from pruning with many multidimensional dominance regions at once. However, of all skyline points, those nearest to C' are likely to prune the most points. (This is the same intuition as for sort-based skyline algorithms [8].) So, we use only the dominance region of a small set of \( n \) nearest neighbors (NN) to C', rather than all skyline points. Algorithmically, the loop on Line 13 is replaced with the assignment, \( u ← \{NN_1, \ldots, NN_n\} \). The optimal number of nearest neighbors to use and the trade-off presented by the approximation is evaluated experimentally in Section 7.

6. CACHE-BASED CONSTRAINED SKYLINE

With the components introduced in Sections 4-5, our Cache-based Constrained Skyline (CBCS) method works as follows. We assume an in-memory cache with \( n \) cache items \( \{I_1, \ldots, I_n\} \), organized by an \( R^d \)-tree indexing the MBR of each cached skyline. Upon receiving a query Sky\( (S, C') \), we perform a search on the \( R^d \)-tree fetching all cache items where \( R_{C'} ∩ MBR \neq \emptyset \). If none exist, Sky\( (S, C') \) is computed naively. If more than one cache item is returned, we select the most efficient based on a cache search strategy (Section 6.1). We then compute the MPR as per Section 5. Finally we fetch the points in the MPR, merge them with the cached Sky\( (S, C) \), and compute Sky\( (S, C') \).

6.1 Cache search strategies

A cache search strategy takes \( m \) query-overlapping cache items \( \{I_1, \ldots, I_m\} \) as input and aims to return the cache item most efficient for computation of the query. We suggest several cache search strategies, which we will compare experimentally in Section 7. Random chooses a cache item uniformly at random among the \( m \) overlapping ones. MaxOverlap chooses the cache item with the highest degree of overlap with the query region. MaxOverlapSP functions as MaxOverlap, except it prefers cache items whose skyline Sky\( (S, C) \) is stable relative to \( C' \) even if there is an unstable option with a higher degree of overlap. PrioritizedID gives preference to simple cases of single changes (as in Sect. 4.2) as follows: Case 2, Case 3, Case 1, General case stable (i.e. not 1D), Case 4 and General case unstable. Ties are broken using MaxOverlap. The case priorities were chosen by experimental evaluation. PrioritizedID(D(C1,C2,C3,C4)) generalizes this case-prioritization idea.
by independently scoring the four cases (i.e., C1 . . . C4) and penalizing cache items for each dimension where constraints differ from the queried. Initial experiments have shown PrioritizednD(10,0,5,20) performs well, thus we use it as PrioritizednD (Std). To demonstrate the importance of proper priorities, we also include a variant PrioritizednD(10,50,30,0) denoted PrioritizednD (Bad). Finally, OptimumDistance chooses the cache item whose lower constraint corner is closest to the lower corner of the queried constraints, to give priority to likely dominating regions.

6.2 Cache replacement & dynamic data
Common cache replacement strategies (i.e., LRU, LCU) are supported by insertion and use counters on the R+ tree. Dynamic data can be supported by viewing each cache item as a separate dataset with a continuous skyline query maintained by any existing method (e.g. [13,19,21]). Due to space constraints, evaluation of cache replacement strategies and dynamic data are omitted from Section 7 and left for future work.

6.3 Multiple cache items
As an extension to the work presented in this paper, one might consider exploiting more than one overlapping cache item during processing. Such a strategy could be beneficial given the increased pruning ability from two cache items. However due to the added complexity, more range queries would be generated, cache search strategies would become more complicated and the number of different overlap cases would require elaborate specialized processing methods. These added complexities merit a separate research effort into such a method and thus we leave this for future work.

7. EXPERIMENTAL EVALUATION
In this section, we provide an extensive experimental evaluation of our CBCS method, investigating scalability, the effectiveness of the approximate MPR, and the cache search strategies. We experimentally compare CBCS to the existing BBS method for computing constrained skylines, as well as a Baseline method that fetches all points in $S_C$ with a range query and applies a standard skyline algorithm (as suggested in [3]). We use the Sort-Filter Skyline (SFS) [8] algorithm in both the Baseline method and our own CBCS method. While more complex skyline algorithms, e.g., BSkyTree [16], might produce faster overall runtimes, our contribution is orthogonal in that the benefit of our CBCS method is independent of the skyline algorithm used, as we show in Section 7.3.

Experiments are performed on Linux with kernel 3.2.0-61-generic, an Intel Core 2 Quad Q8400 2.66 Ghz CPU and 8 GB memory. All algorithms are implemented in Java, using a publicly available Java-based R-tree implementation 2. Data is stored in PostgreSQL 9.1.13 with each dimension indexed by a standard B-tree. The cache is implemented as a simple in-memory cache, organized through an R+ tree that indexes the MBR for each cache item.

All methods are evaluated in separation with the DBMS restarted between runs for fair comparison. In preliminary experiments, we also tested a baseline using sequential scan, but it was consistently slower than the baseline using the indexes; so, we omit it for space.

We evaluate with synthetic data by generating independent, correlated and anti-correlated data using the standard generator from [3]. For real data we use a Danish real estate dataset covering almost 4.2 million properties in Denmark as of 2005. The full 2005 dataset is not publicly available but the current 2013 version can be browsed online 3.

7.1 Query workload generation
Existing constrained skyline work does not study sets of queries, but only single queries. We therefore construct a query generator mimicking interactive search patterns as studied also in relation to constrained skyline queries earlier [6, 17]. The generator chooses an initial set of constraints for each $i \in D$ with $C[i]$ and $\bar{C}[i]$ set randomly between 0 and 3 standard deviations from the mean of dimension $i$, modeling that, for example, average-sized houses are most likely to be searched. Subsequent constraint changes are modeled as follows: 1) The dimension to vary is chosen randomly; 2) whether to increase/decrease lower/upper constraints is chosen at random; and 3) a new query is generated from the old, with a 5% – 10% change in the chosen dimension and direction. Step 3) is repeated 10 times to mimic an interactive scenario with one user posing several similar queries. All steps are repeated until the desired number of queries has been generated.

We evaluate all methods with two different query workloads: (1) the aforementioned Interactive exploratory search and (2) Independent queries in a multi-user system. Workload (1) assumes an empty cache and uses the generator to create 5 independent sets of 100 queries mimicking 5 × 100 actions in an interactive exploratory search. Workload (2) assumes a preloaded cache with 2000 queries, where we receive a number of new independent single queries each generated like the initial query in the generator. Unless stated otherwise locally, the cache search strategies used are MaxOverlapSP for interactive exploratory search queries and PrioritizednD (Std) for independent queries.

7.2 Interactive Search - Dataset size & Dimensionality
Figures 5a-5c show the average running time of our CBCS using aMPR compared to BBS and Baseline, for increasing dataset size on 5D data. Initial experiments showed using 1 NN for aMPR gave the most consistently good results for interactive search scenarios. CBCS average performance is labeled aMPR, further broken down into aMPR (Stable) and aMPR (Unstable) for performance on stable/unstable cases respectively. Results are averaged over the same 5 × 100 interactive exploratory search query sequences. For distributions we see that all methods scale approximately linearly. This is expected since the same range query will require a linear amount of data processing for each increase in dataset size, regardless of the resulting constrained skyline. By comparing Baseline to the CBCS methods, we also see that we scale significantly better than the Baseline on average for all distributions, especially when the cached skyline is stable relative to the queried constraints in aMPR (Stable). In these cases, a partial skyline result requires fetching only a small subset of what Baseline fetches. Thus we both read fewer points and conduct fewer dominance tests. However, while aMPR scales well on average and the stable cases in aMPR (Stable) scale very well, the unstable cases in aMPR (Unstable) fare less well. As discussed in Section 4.2, instability can cause reevaluation if a cached skyline point falls outside of the new constraints. Still, the only case in which the aMPR (Unstable) does not outscale Baseline is on independent data with $\geq 2M$ points.

Interestingly, BBS performs worse than Baseline in several cases and consistently for independent data. This is most likely due to the overhead in R-tree queries when few entire regions are pruned or included in the skyline. As a final note, observe the scales in Figures 5a-5c differ and that, perhaps surprisingly, correlated data is more of a challenge for the methods than independent data. Broadly speaking independent data is evenly distributed and correlated data is grouped in sections of the dataspace. The same queries that returned a given number of datapoints for the independent data
can thus return significantly more for correlated data, if the queries happen to cover where the data is most concentrated. This is exactly what we see here, since the average number of points read is 7 times higher for correlated data than for independent data. Note that despite this, the performance of each method is not reduced 7 times, because the computation of the skyline on correlated data points is much faster.

Figure 6 shows the same experiment as in Figures 5a-5c but for a 3-, rather than 5-, dimensional independent dataset. We include the exact MPR with a stable/unstable split as well as aMPR. Just as in Figure 5a, we see that BBS, Baseline and aMPR all scale linearly. However while BBS performs better, the Baseline is still faster for independent data, since the increased efficiency of the R-tree in \(|D| = 3|S| = 8\) is equally matched by the benefit of simpler dominance tests in the Baseline. The aMPR method remains superior to the Baseline as in Figure 5a, but due to the decreased dimensionality even unstable cached skylines in aMPR (Unstable) are scaling well. Finally the use of the exact MPR rather than the aMPR means stable cache items yield superior results since MPR prunes more of the search space than aMPR. However while the same superior pruning applies to unstable cache items, the MPR method is significantly slower than the aMPR, since cache invalidation yields a prohibitive amount of range queries with subsequent random access latency for MPR. We will discuss a further breakdown of these performance factors for aMPR and MPR in Section 7.3. Finally we observe scalability with regard to \(|D|\) in Figure 7. Note that, unlike unconstrained skyline queries, fixing the dimensionality in constrained skylines has some important implications. Depending on the constraints, adding a dimension may in fact increase the efficiency of a constrained skyline query by reducing the input size. In order to avoid such arbitrary effects, we expand the queries from Figures 5a-5c by adding an unconstrained dimension to each query for each dimension over 5. The dimensionality results for \(|D| = 8\) are thus constrained on 5 dimensions and unconstrained on 3.

As expected, all methods deteriorate exponentially with \(|D|\) as the skyline size increases. For BBS, the performance of the underlying R-tree degrades and for the aMPR, the number of range queries generated increases (see Section 7.3).

7.3 CBCS performance breakdown

We further analyze CBCS by investigating 3 key factors: the number of points fetched, the number of range queries issued, and the types of constraint changes.

7.3.1 Number of points read from disk

Figure 8a shows points read by Baseline and aMPR for the experiment from Figure 5a. The number of points read by Baseline increases significantly with dataset size, while the increase for aMPR is limited except for the unstable cases in aMPR (Unstable). This is key to the performance of aMPR since the number of points read is primarily influenced by the difference in cardinality between sets.
\[ S_C \text{ and } S_{C'}, \text{ rather than the actual size of each set. The larger } \]
\[ \text{increase for } a\text{MPR (Unstable)} \text{ arises both from the likelihood of } \]
\[ \text{cached skyline points being outside the queried constraints and increasing the number of new points included due to invalidation inside the cache item.} \]

Figure 8, which shows the average number of points read from disk for Baseline, aMPR and MPR in comparison, corresponding to Figure 6. The same pattern as in Figure 8a can be seen for Baseline relative to aMPR, while MPR consistently reads fewer points than aMPR from disk, since it is the minimal set. While an unstable cached skyline yields relatively many reads for aMPR, the exact opposite is the case for MPR. This illustrates that while computing the exact invalidation of a cache item is computationally expensive, the extent of invalidation is limited.

### 7.3.2 Number of range queries generated

Figure 9 shows the average number of range queries for MPR and aMPR with 1.3.6 and 10 NNs on interactive (Figure 9a) and independent (Figure 9b) workloads. Both graphs use logarithmic scales and the dataset is limited to 5k points so that we can scale MPR to higher dimensions. Figure 9a reveals that the exact MPR quickly generates extra queries as \(|D|\) increases, e.g., a 6D query/cache item pair generates almost 10k disjoint range queries to cover the MPR. This number would be even higher for \(> 5K\) points. For the aMPR, the reduced hyperplane splitting, while increasing the number of points read, greatly decreases the amount of queries generated dependent on the amount of NNs used. Note that we did not include results for MPR for dimensionalities 8,9 and 10, since just generating the range queries here took several hours for each query. Thus the approximation really improves scalability as \(|D|\) increases.

Figure 9b confirms these trends for independent queries as well, but both methods generate more queries and the increase is more rapid, because the queries generated overlap less in higher dimensions. Observe that the number of NNs can be used to manipulate the tradeoff between reading few points from disk and decreasing random access. While large quantities of range queries seem problematic, they do not necessarily deteriorate the performance of the method. Considering e.g. Figure 9b for \(|D|=4\) and \#NN=10, on average \(\approx 61\) queries were generated for aMPR, but the number actually reading data only averaged 33. The remaining queries were discarded by the DBMS without any disk seeks because the B-trees detect the empty queries. For \(|D|=10\) and \#NN=10 these numbers increase to 13353 queries generated of which only 114 read data from disk.

Note that with only 5K, no stable cases were generated for \(|D|>4\). From Theorem 1, this is not surprising, since just one dimension \(i\) where \(\mathbb{C}_i \leftarrow v > \mathbb{C}_i [i]\) causes instability of Sky\(|S, C_0|\) relative to \(C\).
So, for independent queries, CBCS methods work best for lower dimensional settings, and shows most benefit for exploratory queries.

7.3.3 Types of constraint changes

Figure 10 breaks down computation for 1M points (settings as in Figure 6) into 3 stages: processing, fetching, and skyline computation, corresponding to the main-memory selection of range queries, the latency to read points from disk, and the running of SFS, respectively. Baseline has no processing stage, but suffers long fetching. Conversely, aMPR has light processing, which reduces fetching and then, having fewer input points, skyline computation. Considering specific types of changes, aMPR Case 2 has no fetching stage or computation stage, since this is a simple case which only requires removing cached skyline points. aMPR Case 3 shows a slight processing stage followed by a significantly smaller fetching stage than both Baseline and aMPR Case 1 since we are able to prune the search space significantly using cached skyline points. Note that while the relative gains of the fetching stage from aMPR Case 1 to aMPR Case 3 are only half, a larger portion of points is pruned, with random access being more time consuming.

To conclude, we see that the superior performance of aMPR and MPR arises primarily from the reduced reads from disk, which reduces both fetching and skyline computation. Also, the performance is independent of the skyline algorithm used, since this is anyway not a bottleneck. Finally we see that the MPR requires too many range queries for mid- to high-dimensional data, but the aMPR generates a small, stable number of range queries independent of the dataset size.

7.4 Cache search strategies

Our last synthetic experiment shows the distribution of response times for each proposed cache search strategy from Section 6.1, using aMPR on 5 × 100 interactive queries (Figure 11a) and 500 independent queries (Figure 11b).

Compared to the Random strategy we can see there is a clear benefit in using overlap as a guiding factor (observe MaxOverlap, MaxOverlapSP and in part Prioritized1D which uses MaxOverlap to settle ties). High overlap yields smaller MPRs, especially in stable cases. On the other hand, prioritizing only stable cases is not a good strategy for independent queries, as is clear from MaxOverlapSP: such queries are likely to vary in several dimensions such that choosing solely on stability may select an item with poor overlap or many changed dimensions. Instead a balanced ranking-based approach like PrioritizednD (Std) is most promising, since it not only considers stability but also case complexity. PrioritizednD

Figure 11: Cache search strategies (|S| = 1M, |D| = 5) (Bad) shows poor performance demonstrating that the case-based scoring is important for performance. Finally, OptimumDistance performs poorly: considering only closeness in terms of dominance fails to capture the complexity of cases and overlap.

7.5 Real data

We study real data covering ~ 4.2 million properties in Denmark as of 2005 using 4-dimensions suitable for constrained skyline computation: year (year of construction), sqm (size in m²), valuation (property tax valuation) and price (actual sales price). The final dataset size is 1.28M records after removing records with missing data. Figures 12a and 12b respectively show the distribution of response times for 10 × 100 exploratory search queries and 50 independent queries. Figure 12a shows our aMPR method is superior to both Baseline and BBS, with BBS managing about 2.2 seconds on average per query and Baseline performing significantly better at about 0.45 seconds. Note the average response time of aMPR (Unstable) is actually low due to limited invalidation, while the worst case invalidation yields response times above the average for Baseline. Figure 12b shows a set of independently generated queries. Here Baseline varies heavily in performance due to varying query selectivities, while BBS is stable with the changing constraints. The remaining 3 plots show aMPR with varying numbers of NNs. The number of NNs chosen in this case has a large impact on performance, since using only 1 as with the ex-
exploratory queries yields poorer results than BBS, while 5 NNs or 10 NNs greatly outperforms it. Using more than 10 NNs however did not provide any significant further benefit in this case.

In conclusion, the major performance factors are the number of disk reads performed and the degree of random access due to multiple range queries. We have shown that CBCS performs substantially better on related queries than existing methods. The performance benefit remains stable for increasing dataset size and dimensionality, when using approximate aMPR. The cache search strategy is a clear determinator of the resulting performance with the main factors being average overlap, stability and case distributions.

8. CONCLUSION

In this paper we introduced a novel method for computing constrained skylines using an in-memory cache. Our method was envisioned under two common types of query workloads with related queries, namely interactive search and multi-user systems. We determined four possibilities for incremental query/cache overlap, analyzed them and presented specialized techniques for each. For general query/cache overlap, we introduced the Missing Points Region, which minimizes points read from disk by exploiting the cache item’s relation to the query. To increase the practical performance of this general method, we introduced a conservative approximation of the MPR, called aMPR, to balance the trade-off between resultant range queries and points read from disk. Finally we introduced a set of heuristics to choose the most efficient overlapping cache item for a query. Our extensive experimental evaluation revealed, among other things, that the choice of cache item to use for processing has a big impact on performance and that our method significantly outperforms existing approaches when related queries are present.

10. REFERENCES

APPENDIX

Proof of Theorem 1. Consider left [L] and right [R] sides of the OR expression. From [R] we have \( \exists i \in D: C'[i] \not\in C[i] \lor C'[i] \not\in \overline{C}[i] \lor C'[i] \not\in \overline{C}[i] \Rightarrow R \cap R' = 0 \), so that Sky(C') is stable in this case. For [L] we prove \( \forall i \in D: C'[i] \leq C[i] \) implies stability, by contradiction. Assume \( \exists i \in Sky(S(C')): (s \not\in Sky(C)) \). From Def 1, this implies \( \exists t \in SC: t \succ s \). This in turn means \( s \in Sky(S(C')) \Rightarrow t \not\in SC \Rightarrow \exists i \in D: C'[i] < t \not\in C' \Rightarrow s \not\in Sky(C') \) contradicting the assumption. Observe that [L] and [R] are the only situations with guaranteed stability, since cases not satisfying Thm 1 must have \( R \cap R' \not\subseteq 0 \) and \( \exists i \in D: C'[i] < C'[i] \leq C'[i] \). Thus for \( u \in Sky(S(C'), C'[i] \not\in C'[i] \not\leq C'[i] \not\leq C[i] \) we could have \( v \in SC \), \( u \succ v \) and \( C'[i] \not\leq C'[i] \not\leq C[i] \). Since \( u \not\in SC \) we might then have \( v \in Sky(S(C')) \), making Sky(C') unstable relative to C'.

Proof of Theorem 2. Since Sky(C) is stable relative to C' given Thm 1, equality follows from Cor 1. Minimality holds since \( \exists s \in Sky(C), t \in SA_C: s \not\succ t \).

Proof of Theorem 3. Observe \( SC \subset SC \) and that Sky(S,C) is stable relative to C' given Thm 1. Thus we must have Sky(C') \not\subseteq Sky(C') and Sky(C') = Sky(C') \cap SC'. Minimality holds since the reduction simply removes cached skyline points and no further reads are necessary.

Proof of Theorem 4. Observe Sky(S,C) is stable relative to C' given Thm 1. Thus equality follows from Cor 1 since for \( s \in Sky(S,C) \) we either have \( s \in Sky(C) \) or \( s \in SA_C \), where \( \exists t \in Sky(C), t \succ s \).

Minimality holds since \( \forall u \in Sky(S,C), v \in \{Sky(S,C) \cup \{s \in SA_C: \exists t \in Sky(C), t \succ s\}: u \not\succ v \}, i.e. we have no further known points to prune SA_C with.

Proof of Theorem 5. Given Thm 1, Sky(S,C) may be unstable relative to C' and we observe \( SC \subset SC \). At this point we have two possibilities given Cor 2: [St] Sky(S,C) is stable relative to C', or [USt] Sky(S,C) is unstable relative to C'. If case [St] holds, then Sky(S,C) = Sky(C) \cap SC since there is no invalidation. If case [USt] holds, then from Cor 2 we have \( \exists \not\in Sky(S,C) \).

Proof of Theorem 6. We prove equality in right [R] and left [L] directions. For [R] we assume \( w \in Sky(C') \). Then we have two cases: [1] \( w \in (R_C \cap R_{C'}) \) and [2] \( w \in (R_{C'} \setminus (R_C \cap R_{C'})) \). i.e. \( w \) is either in the overlapping region between cache and query [1] or outside the cache [2].

If we have case [1], then given Cor 2 we have \( w \in (Sky(S,C) \cap R_{C'}) \lor \exists t \in Sky(S,C) \lor \exists \not\in Sky(S,C) \). For the opposite direction, [L], we assume \( w \in Sky(S(C'),SC) \lor (MPR \land SC') \). We then have two cases: [St] Sky(S,C) is stable relative to C', and [USt] Sky(S,C) is unstable relative to C'.

If we have case [St], then given Cor 1 we have \( w \in (Sky(S,C) \setminus SC') \lor (w \in (R_{C'} \setminus R_C)) \), i.e. \( w \) is either a cached skyline point or outside the cache.

If instead we have case [USt], then given Cor 1 and 2, we have \( (w \in Sky(S,C) \setminus SC) \lor \exists \not\in Sky(S,C) \lor \exists t \in Sky(S,C) \lor (w \in (R_{C'} \setminus R_C)) \). We then have two cases [1] \( \exists \not\in Sky(S,C) \) and [2] \( \exists t \in Sky(S,C) \).

If [1] then \( w \in Sky(S,C) \land \exists \not\in Sky(S,C) \lor \exists t \in Sky(S,C) \lor \exists \not\in Sky(S,C) \lor \exists \not\in Sky(S,C) \) which implies \( w \not\in Sky(S(C'),SC) \lor (MPR \land SC') \) given Def 1 yielding a contradiction.

If [2] then \( \exists \not\in Sky(S,C) \lor \exists \not\in Sky(S,C) \lor \exists \not\in Sky(S,C) \lor (w \in Sky(S,C) \setminus SC) \lor \exists \not\in Sky(S,C) \lor \exists \not\in Sky(S,C) \lor \exists \not\in Sky(S,C) \) which implies \( w \in Sky(S(C'),SC) \lor (MPR \land SC') \) given Def 5, also yielding a contradiction. Hence \( w \in Sky(S,C) \).
